ABSTRACT: Direct solar-powered production of value-added chemicals from CO₂ and H₂O, a process that mimics natural photosynthesis, is of fundamental and practical interest. In natural photosynthesis, CO₂ is first reduced to common biochemical building blocks using solar energy, which are subsequently used for the synthesis of the complex mixture of molecular products that form biomass. Here we report an artificial photosynthetic scheme that functions via a similar two-step process by developing a biocompatible light-capturing nanowire array that enables a direct interface with microbial systems. As a proof of principle, we demonstrate that a hybrid semiconductor nanowire–bacteria system can reduce CO₂ at neutral pH to a wide array of chemical targets, such as fuels, polymers, and complex pharmaceutical precursors, using only solar energy input. The high-surface-area silicon nanowire array harvests light energy to provide reducing equivalents to the anaerobic bacterium, Sporomusa ovata, for the photoelectrochemical production of acetic acid under aerobic conditions (21% O₂) with low overpotential (η < 200 mV), high Faradaic efficiency (up to 90%), and long-term stability (up to 200 h). The resulting acetate (∼6 g/L) can be activated to acetyl coenzyme A (acetyl-CoA) by genetically engineered Escherichia coli and used as a building block for a variety of value-added chemicals, such as n-butanol, polyhydroxybutyrate (PHB) polymer, and three different isoprenoid natural products. As such, interfacing biocompatible solid-state nanodevices with living systems provides a starting point for developing a programmable system of chemical synthesis entirely powered by sunlight.

KEYWORDS: Nanowires, artificial photosynthesis, bacteria, carbon dioxide fixation

Natural photosynthesis, which harvests 130 TW of solar energy to generate up to 115 billion metric tons of biomass annually from the reduction of CO₂, provides motivation for the development of artificial systems that can capture the energy of the sun to convert CO₂ and H₂O to value-added chemicals of societal benefit. However, such an approach has not been fully realized owing to a host of unmet basic scientific challenges. For example, enzymes isolated from microorganisms and plants can selectively catalyze CO₂ reduction with low energy barriers; however, they do not self-repair outside their native cellular context and are often intolerant to oxygen. Consequently, bioderived CO₂-reducing catalytic systems are not directly applicable to oxygen-containing CO₂ sources such as flue gas. Another challenge for artificial photosynthesis is the selective synthesis of complex organic molecules. Nature transforms CO₂ into a variety of complex molecules using a limited number of biosynthetic intermediates as building blocks. However, in the case of artificial photosynthesis, the selection of such an intermediate is difficult: ideally, mass transport requires it to be water-soluble, and it should also be easily incorporated into many biosynthetic pathways.

We sought to develop a strategy for artificial photosynthesis, where biocatalysts in their native cellular environments are interfaced directly with semiconductor light-absorbers for unassisted solar CO₂ reduction. Specifically, we envisioned a two-step strategy that mimics natural photosynthesis, where light capture by a biocompatible nanowire array can interface and directly provide reducing equivalents to living organisms for the targeted synthesis of value-added chemical products from CO₂ fixation (Figure 1). Such an integration between
materials science and biology separates the demanding dual requirements for light-capture efficiency and catalytic activity, respectively, and provides a route to bridge efficient solar conversion in robust solid-state devices with the broad synthetic capabilities of living cells. This artificial photosynthesis strategy is distinct from the active area of microbial electrosynthesis, in that the nanomaterials carry out both light-harvesting and delivery of reducing equivalents. Here, as a first step, we demonstrate a stand-alone, solar-powered system composed of silicon (Si) and titanium dioxide (TiO₂) nanowire arrays as the light-capturing units and S. ovata as the cellular catalyst, which can effectively reduce CO₂ under mild conditions (e.g., aerobic atmosphere, neutral pH, and temperatures under 30 °C) and produce acetate for up to 200 h under simulated sunlight, with an energy-conversion efficiency of up to 0.38%. Such a system, where CO₂-reducing bacteria are directly interfaced with a photoactive semiconductor, to the best of our knowledge, represents the first example of microbial photoelectrosynthesis, which is different from conventional microbial electrosynthesis wherein microbes do not directly interact with light-absorbing devices. The nanowire–bacteria hybrids possess a high reaction rate of CO₂ reduction, and the presence of the nanowire array creates a local anaerobic environment that allows strict anaerobes to continue CO₂ reduction aerobically (21% O₂), which is important for practical application. Finally, the acetate intermediate represents a biosynthetic precursor to a wide variety of potential fine and

Figure 1. Schematics of a general artificial photosynthetic approach. (a) The proposed approach for solar-powered CO₂ fixation includes four general components: (1) harvesting solar energy, (2) generating reducing equivalents, (3) reducing CO₂ to biosynthetic intermediates, and (4) producing value-added chemicals. An integration of materials science and biology, such an approach combines the advantages of solid-state devices with living organisms. (b) As a proof of concept, we demonstrate that under mild conditions sunlight can provide the energy to directly treat exhaust gas and generate acetate as the biosynthetic intermediate, which is upgraded into liquid fuels, biopolymers, and pharmaceutical precursors. For improved process yield, S. ovata and E. coli are placed in two separate containers. FPP = farnesyl pyrophosphate.
commodity chemicals via acetyl coenzyme A (acetyl-CoA), including functionalized aliphatics and aromatics, lipids, alkanes, and complex natural products. By simply selecting specific genetically engineered E. coli strains, our strategy of artificial photosynthesis can be programmed to produce a variety of products with minimal modification, providing a versatile and amenable platform for solar-driven CO₂ reduction to value-added fuels, chemicals, and materials.

The system starts by interfacing light-absorbing Si nanowire arrays with an acetogenic organism, S. ovata. Si nanowire arrays capture light for efficient solar energy conversion and provide high surface areas to interface with catalysts. The strictly anaerobic homoacetogen S. ovata metabolizes CO₂ via the energy-efficient Wood–Ljungdahl pathway and has been reported to accept electrons from graphite electrodes to reduce CO₂ into acetic acid. The integration was realized by directly culturing S. ovata within a Si nanowire array passivated by a 30 nm TiO₂ protection layer, using buffered brackish water medium with trace vitamins as the only organic component (see Methods, Supporting Information Figure 1a). After an initial incubation period, a steady-state nanowire bacteria hybrid structure was formed. In such a structure, the bacteria formed an interconnected network among the nanowires (Figure 2a and Supporting Information Figure 2). Careful characterization with scanning electron microscopy (SEM) indicates that bacteria populate the array quite uniformly without apparent mass transport issues (Figure 2b,c). The cell loading of S. ovata within the nanowire array is 4.4 ± 1.0 times of that observed on a planar Si electrode (1.4 ± 0.1 vs 0.32 ± 0.07 cells per geometric μm², n = 4) (Supporting Information Figure 2d), revealing increased contact interfaces between bacteria and electrodes in this high-surface-area platform. The proposed half-reaction of CO₂ reduction is

\[
2\text{CO}_2 + 7\text{H}^+ + 8\text{e}^- \rightarrow \text{CH}_3\text{COO}^- + 2\text{H}_2\text{O}
\]

\[E^\circ = +0.143 \text{ V vs RHE}\]

From a classic electrochemical analysis without solar illumination (Figure 2d), the nanowire–bacteria hybrids were capable of reducing CO₂ to acetate under continuous sparging with 20% CO₂/80% N₂ with an overpotential η less than 200 mV at 0 V vs reversible hydrogen electrode (RHE) (see Methods), similar as reported in the literature. Additionally the Tafel slope of bacterial catalyzed CO₂ reduction is distinctly different from that of abiotic proton reduction, implying different reaction mechanisms (n = 2). On average, each cell could produce (1.1 ± 0.3) × 10⁷ molecules of acetate every second or ca. 10²² molecules of acetate over the course of about 5 days at −0.2 V vs RHE (Supporting Information Figure 2c,d), comparable with its intrinsic rate of acetogenic metabolism (Supporting Information Note). Such nano-biohybrids, which operate at ambient temperature, possess a volumetric reaction rate of ca. 2 mol m⁻³ s⁻¹, comparable to the rates in conventional gas phase catalysts (0.1–10 mol m⁻³ s⁻¹) that require much higher temperatures (higher than 100 °C). It also corresponds to ca. 8 electrons s⁻¹ nm⁻² across the semiconductor/electrolyte interface (at −0.2 V vs RHE), suitable to couple with efficient solar devices at 10 mA/cm² when integrated into a high-surface-area electrode.

The high reaction rate of the nanowire–bacteria hybrids allows us to construct a solar-powered CO₂-reduction device for the production of acetate as a common biosynthetic

![Figure 2.](image-url)
feedstock (Figure 1a). Analogous to the two photosystems found in nature, Si and TiO₂ nanowires were applied as two robust semiconductor light-absorbers to provide the thermodynamic driving force for CO₂ reduction. Specifically, an ion-conductive membrane was placed in between the two electrodes to separate reaction products, and the water-oxidizing TiO₂ nanowire electrode was placed in front of the nanowire-bacteria composite to absorb UV light and prevent possible bacterial photodamage (Figure 1a and Supporting Information Figure 1b). Without any additional energy input, nonzero photocurrent was observed (light chopping experiment in Figure 2e), and CO₂ reduction to acetate was confirmed (see Methods). The overall system produced about 0.3 mA/cm² photocurrent under simulated sunlight (AM 1.5G, 100 mW/cm²) and was stable for more than 120 h (Figure 2e, and the photocathode in Supporting Information Figure 3). Starting from an electrolyte free of organic compounds, acetic acid was steadily produced with a product selectivity (Faradaic efficiency) of 86 ± 9% (n = 6) (Figure 2e). The peak photocurrent reached 0.35 mA/cm², which corresponds to an energy conversion efficiency of 0.38% for acetic acid production (requires 1.08 V thermodynamically, see Methods). The acetic acid titers were ca. 1.2 g/L (20 mM) within 5 days and could reach over 6 g/L (ca. 100 mM) in M9-MOPS minimal medium (see Methods and Supporting Information Note). In separate control experiments, no acetic acid was detected without incorporation of S. ovata, and an isotope-labeling experiment proves that the acetate is produced from CO₂ (Supporting Information Figure 4). These results highlight our ability to upgrade CO₂ to chemicals beyond one-carbon targets. In next-generation designs, we are targeting even higher efficiencies through further improvement on peripheral limitations such as CO₂ mass transport in the electrolyte and the large band gap of the photoanode. Nevertheless, it represents a unique materials—biological hybrid for artificial photosynthesis, which demonstrates unassisted light-driven CO₂ fixation to acetic acid.

An interesting benefit of the nanowire array arises from its selective control of mass transport within the wire assembly. Specifically, the design of nanowire—bacteria hybrids allows for the continuation of CO₂ reduction, a reaction catalyzed by strict anaerobe S. ovata, under a headspace containing 21% oxygen when an oxygen reduction reaction electrocatalyst (in the current case, Pt, see Methods) was loaded. The similar Tafel slopes of CO₂ reduction for planar and nanowire electrodes (Figure 2d) inform us that mass transport of protons and CO₂ was not a limiting factor within the nanowire array. However, with its limited solubility in water, oxygen can be depleted within the nanowire array logarithmically, distinctly different from a planar counterpart (Supporting Information Note and Figure 5a,b). This arrangement effectively creates a local anaerobic environment at the bottom of the nanowire arrays, as supported by numerical simulation (Figure 3a and Supporting Information Figure 5c). Experimentally, after S. ovata had colonized the electrode anaerobically, we switched to an aerobic gas environment with 21% oxygen partial pressure (21% O₂/10% CO₂/69% N₂) (see Methods). Only the nanowire array loaded with Pt maintained its ability to reduce CO₂ and consistently produce acetic acid with a Faradaic efficiency of about 70% (t = 85 h, Figure 3b). Compared to the data obtained under anaerobic conditions (20% CO₂/80% N₂), the loss of Faradaic efficiency observed under aerobic conditions (~15%) is related to the oxygen reduction reaction (Supporting Information Figure 6), which can be greatly minimized with improved design of the nanowire—bacteria hybrids (Supporting Information Note). In general, our observation implies that (1) in our system most, if not all, of the acetate is produced from bacteria interfacing directly with nanowires and (2) combining nanowire arrays with CO₂-reducing microorganisms can allow anaerobes to be used in a wider range of applications, such as CO₂ scrubbing from exhaust gas or even open air operation.

Taking advantage of the power of synthetic biology, a wide spectrum of complex organic molecules was synthesized by directly using the solar-derived acetate from oxygen-containing CO₂ feedstock. Under aerobic or microaerobic conditions, genetically engineered E. coli can activate acetate into the common biochemical intermediate acetyl-CoA, which then will
be used for the biosynthesis of a variety of complex molecules. Here the names of proteins are listed, and the colors differentiate their genetic origins. In addition to these described pathways, some of the acetyl-CoA are expected to be diverted into the TCA cycle for redox balancing. (b) Solar-derived acetic acid from nanowire–bacteria hybrids was used as the feedstock to yield a variety of chemicals in M9-MOPS medium ($t = 5$ days). No organic substrates were provided except the solar-derived acetic acid, and the acetate-containing medium solution was produced under aerobic conditions (21% O$_2$/10% CO$_2$/69% N$_2$) using simulated sunlight. Here $X_{\text{product}}$ is acetate-to-product conversion efficiency; $n = 3$ for all reported values. The results reported here outline a solar-energy conversion process that combines the strengths of semiconductor nanodevices and bacterium-based biocatalysts (Figure 1a). Key advantages of the nanowire-based device are the enhanced oxygen tolerance that allows exhaust gas to be directly fed into the system, thereby enabling use of strict anaerobes with aerobes, as well as the high measured CO$_2$ fixation activity of the nanowire–bacteria hybrid. Moreover, this modular platform simplifies the overall system design by allowing for the production of a variety of molecular targets, without any setup change in the components for light capture and CO$_2$ reduction into acetate, by varying only the downstream microorganisms.
